Abstract

Objective: The present study was undertaken to assess diagnostic role of High Resolution Multi-detector Computed Tomography (HRMDCT) of temporal bone in the evaluation of Chronic Suppurative Otitis Media (CSOM) and to correlate intraoperative and HRCT findings in CSOM in selective cases

Material and Methods: In our prospective study, a total of 57 who presented with CSOM and referred to Radiodiagnosis department were included in this study. The suspected patients were subjected to HRMDCT of Temporal bone using GE Bright speed Elite16 multi slice CT machine with 0.6mm plain axial and coronal slices with multiplanar reformations.

Results: The reported findings were correlated with clinical and surgical findings in subset of cases. Sensitivity, Specificity of HRMDCT with respect to clinical and surgical correlation in selective cases was evaluated. Among 30 surgical cases, most of them were atticocanal (53.4%) followed by tubotympanic CSOM (46.6%). On surgical correlation, HRCT has a high sensitivity (84.36%), specificity (80%), PPV of 90.4% and accuracy of 90% in the diagnosis of type of CSOM. A significant association with p value<0.05 was seen for cholesteatoma, ossicle, bone, mastoiditis, scutum, tegmen and prussack space involvement. HRCT had a high sensitivity and specificity in detection of cholesteatoma (86.4%, 88.9%).

Conclusion: HRCT of Temporal bone has a good sensitivity, specificity in the diagnosis of type of CSOM with respect to surgical correlation. HRCT of Temporal bone affords essential information regarding the disease extent, associated complications, aiding clinicians in deciding the appropriate surgical planning and management, thereby making HRMDCT an essential pre workup diagnostic tool.

Keywords: Cholesteatoma, CSOM, HRMDCT, Prussack space, Temporal bone.

Introduction

Chronic suppurative otitis media (CSOM) is a chronic inflammation of the tympanic cavity with potential for mastoid extension and further complications. CSOM and resultant hearing loss of 60%1 remains a significant health problem with
high prevalence of >4% in India. 60% patients with CSOM usually have cholesteatoma\textsuperscript{1,2}. Early identification is needed to adopt the appropriate surgical procedure and to prevent hearing loss and complications. The petrous temporal bone is a highly developed sophisticated structure with minute middle and inner ear structures. Therefore, it is difficult to evaluate temporal bone with imaging modalities like radiograph, routine CT of head and MRI, hence led to the adoption of HRMDCT as an essential tool in the evaluation of middle ear pathology\textsuperscript{3}.It gives essential information about bony details and soft tissue density\textsuperscript{4}. Therefore the aim of this study was determine the diagnostic role of High Resolution Multi-detector Computed Tomography (HRMDCT) of temporal bone in the evaluation of Chronic Suppurative Otitis Media (CSOM) and to correlate intraoperative and HRCT findings in CSOM in selective cases.

**Material and Methods**

In our prospective, descriptive study, we evaluated 57 cases with CSOM in the age group of 6 -70 years who were referred from ENT outpatient Department and further referred to Department of Radiodiagnosis were selected randomly for the study, following all the inclusion and exclusion criteria. The study was conducted after obtaining prior approval from institutional ethical committee. The duration of the study was from January 2018 to June 2019.

**Inclusion Criteria**

Patients of both sexes and all age groups presenting with CSOM to ENT outpatient Department and referred to Department of Radiodiagnosis were randomly included in this study.

**Exclusion Criteria**

Patients with history of previous surgery for CSOM, patients with a history of prior temporal bone trauma, patients with ear implants, patients with otitis externa and patients with vascular lesions. As soon as the patient presented to the hospital, detailed clinical history, preliminary lab investigations and clinical examination were carried out and documented. Suspected cases with symptoms such asotorrhea, otalgia, hearing loss, clinical and otoscopic findings such as granulation tissue, retraction pockets, and tympanic membrane perforation were referred to Department of Radiodiagnosis for HRMDCT for further evaluation. All the study patients were thoroughly explained about the study procedure and after obtaining a written inform consent from each patient important clinical, otoscopic findings were recorded in the proforma.

In our department, each scan was obtained on a GE bright speed Multi12 16-section spiral/helical CT scanner. First, lateral topogram was taken followed by helical acquisition was done in axial, coronal and sagittal planes. 0.6mm plain axial slices with multiplanar reformations and bone algorithm were done. The scan was performed from the level of inferior mastoid to arcuate eminence. The scanning angle was 30 degree to baseline and parallel to lateral semi-circular canal. The studies were performed with the mentioned parameters: 2 mm collimation, 120 kVp, 140 mAs, a pitch of 0.8, 15-cm field of view and a 512 x 512 matrix. The image data set was reconstructed into magnified axial, sagittal, and coronal images with 0.1mm thickness at an interval of 0.312 mm with overlap. A window width of 4000HU was used. All images were studied and interpreted on the GE workstation using the source and multiplanar reformatted images (images 1-7). Contrast study was advised when intracranial complications were present/suspected.

The HRCT findings were reported, correlated and tabulated with clinical findings in the proforma. A subset of 30 patients who underwent surgery during this study period was considered for surgical correlation. All the intraoperative findings were collected and correlated with HRCT findings in the proforma. All cholesteatoma cases were histopathologically diagnosed. Data Analysis was done in the form of proportion or percentage. Sensitivity and Specificity of...
MDHRCT, with respect to clinical and surgical correlation in selected cases were evaluated. Association between categorical variables tested by using chi – square test /Fischer exact test .Value p (<0.05) were considered to be statistically significant. SPSS software was utilized for analysis of collected data.

**Results**

All radiological findings were tabulated and correlated with intra-operative findings. False positive, false negative, sensitivity, specificity and P value were statistically analysed and tabulated as shown in table 1 and 2. Association between categorical variables was tested by using chi – square test Value p (<0.05) were considered to be statistically significant. Among the 30 surgical cases, most of them were atticoantral (53.4%) followed by tubotympanic CSOM (46.6%). On surgical correlation, HRCT has a high sensitivity of 84.36%, specificity of 80%, Positive Predictive Value (PPV) of 90.4% and accuracy of 90% in the diagnosis of type of CSOM. It had less Negative Predictive Value (NPV) of 72.7% due to the false negatives. P value (<0.05) was considered to be statistically significant (Table 1). A significant association with p value <0.05 was seen for cholesteatoma, ossicle, bone, mastoiditis, scutum, tegmen and prussack space involvement. HRCT had a high sensitivity and specificity in the detection of cholesteatoma (86.4%,88.9%), overall bone erosion (89.3%, 91.6%), incus erosion (83.3%, 100%), Prussack space involvement (92.8%,100%), tegmen erosion (100%,100%), scutum(95%, 100%), semicircular canal erosion (80%, 100%), mastoiditis, tympanic membrane perforation (81.8%,85.7%), intracranial complications (83.3%,100%) like osteomyelitis, cerebellar abscess and petrous apicitis. HRCT had moderate sensitivity in detecting overall ossicular erosion (76%), malleus (60%), stapes(72.3%), sinus tympani(66.6%), facial canal (69.2%), attic/aditus/antrum (70-75%), dural plate(75%) and sigmoid plate (66.6%) involvement(Table2).

Out of 30 (100%) operated cases (Gold standard), 19 cases were atticoantral CSOM of which 16 cases (53.4%) were correctly diagnosed by HRCT. Intra operatively, 11cases were tubo tympanic whereas on HRCT 14 cases (46.6%) were diagnosed as tubotympanic CSOM. Therefore HRCT has a Sensitivity of 84.4%, Specificity of 80%, PPV of 90.4%, NPV of 72.7% and accuracy of 90% in the diagnosis of type of CSOM.

Discussion
In our present study, out of 30 (100%) operated cases (Gold standard), 19 cases were atticoantral CSOM and 11 cases were tubotympanic CSOM intraoperative. 16 cases were atticoantral (53.4%) and 14 cases (46.6%) were diagnosed as tubotympanic CSOM on HRCT. Accordingly, out of the operated cases atticoantral CSOM was seen in majority with 16 cases (53.4%) similar to the findings of PayalS et al and CL Thukral et al studies. HRCT had a sensitivity of 84.4%, specificity of 80%, Positive Probability Value (PPV) of 90.4%. Negative Probability Value (NPV) of 72.7% was due to the false negatives. Sunitha Dashottar et al study had good NPV, but low specificity. However, Mariam Aljehani et al study had 100% sensitivity and specificity. 100% sensitivity and 95% specificity was seen in Prabhu et al study.

The accuracy of HRCT was 90% in this study similar to Prabhu et al study with accuracy of 95% and the results showed a significant association with p value 0.16 (p<0.05) and chi square statistic of 12.4 was seen for cholestestoma, bone erosion, ossicular erosion, mastoiditis, tegmen, scutum and prussack space involvement. These results were comparable with other studies.

The study also showed that out of 30 operated cases, 19 cases had cholesteatoma out of which 16 were detected by HRCT. The two false positives were likely due to non cholesteatomatous atticoantral disease as quoted in their review article. Most of the false positives were due to inability to differentiate granulation tissue from cholesteatoma or non cholesteatomatous type of atticoantral CSOM as quoted by Walsh et al in their study. Two cases of false negatives were found in mesotympanum followed by hypotympanum (1 case). Most of the false negatives were seen in mesotympanum with a sensitivity of 70%. and Hypotympanum soft tissue density has less sensitivity of 68% in a similar study.

In the present study HRCT showed a high sensitivity of 86.4% and specificity of 88.9%
detecting the cholesteatoma/atticoantral disease. Our results were comparable with previous study\textsuperscript{9}. Buta high sensitivity (100%) and specificity (95%) were reported in similar previous studies\textsuperscript{2,4,7}. However, Wang EL et al\textsuperscript{14} study showed less sensitivity (65%) and specificity (72%) in identifying cholesteatoma and they stated that it was due to HRCT inability to differentiate it from soft tissue density based on Hounsfield Units (HU) value alone. Vinith Kumar Sharma et al\textsuperscript{15} in their study quoted that HRCT is less accurate in differentiating the granulation tissue from cholesteatoma and requires clinical correlation. Bone erosion was seen in 25 cases intra operatively of which 22 cases were detected by HRCT. The two false positives were present in tubotympanic CSOM. False negatives (2 cases) were seen in tubotympanic type, and were seen in ossicle involvement. Hence, HRCT had a high sensitivity of 89.3% and specificity of 91.6% in detecting the bone erosion. These findings are comparable with previous study\textsuperscript{13} which showed high sensitivity 80% and specificity 100% respectively.

Similarly, ossicular erosion was seen in 19 cases intra operatively of which 13 cases were detected by HRCT in the present study. Two false positives were present in tubotympanic CSOM. Majority of false negatives (4 cases) were seen in tubotympanic type. Hence HRCT had less sensitivity of 76% but high specificity of 86.6% in detecting the ossicular erosion and these findings are in concurrence with earlier study\textsuperscript{16}.

HRCT has shown a less sensitivity 72.3 % but high specificity 83.3% in the detection of stapes erosion. One false positive was seen involving supra structure of stapes. Majority of false negatives (2 cases) had foot plate erosion. Payal G et al\textsuperscript{17} quoted that the false negatives were due to tissue partial volume averaging phenomenon and soft tissue around the supra structure of stapes makes it difficult to visualize. Their study also quoted that foot plate of stapes has poor visualization. Sunita Dashottar et al\textsuperscript{7} in their study had less sensitivity of 68%. Whereas Poor kappa value of 0.3-0.5 was seen in Zhang X et al\textsuperscript{18} study and Sonika et al\textsuperscript{12} study had good sensitivity 90% and 100% specificity.

In our study, HRCT has shown a high sensitivity 83.3% and specificity 100% in the detection of incus erosion with no false positives being present similar to other study findings\textsuperscript{9} with sensitivity 85.7% and 100% specificity. However, false negatives (2 cases) were seen involving lentiform process in majority. Payal G et al\textsuperscript{17} in their study quoted that most of the false negatives involved the lentiform process which is the most common site of ossicular erosion and is a subtle finding.

In the detection of malleus erosion. HRCT has less sensitivity 60% and specificity 85.7%. One false positive was seen involving manubrium/handle of malleus. False negatives were seen involving manubrium (4 cases) followed by lateral process (2cases) and head (1 case). Sunitha Dashottar\textsuperscript{7} and Karkhi S et al\textsuperscript{20} had a sensitivity of 60%. However, in Tripti Rai\textsuperscript{13} study, good sensitivity 100% and specificity100%. Amy F Juliano et al\textsuperscript{21} in their study quoted most often the manubrium of malleus are early sites of cholesteatoma erosion and is a subtle finding.

Prussack space involvement was seen in 13 cases out of which 12 cases were detected by HRCT. False negative was seen associated with soft tissue density in mesotympanum (pars tensacholesteatoma). HRCT has a high sensitivity 92.8% and specificity 100% in the detection of prussack space involvement. Similar results were seen in Hassmann Poznanaska et al\textsuperscript{22} study with sensitivity of 87% and specificity of 100% and the false negatives were due to pars tensacholesteatoma with marginal perforation. Bernadette Koch et al\textsuperscript{23} in their book have quoted that Prussack space involvement less commonly occurs in pars tensacholesteatoma.

HRCT has a high sensitivity 95% and specificity 100% in the detection of scutum erosion where in Scutum erosion was seen in 19 cases of which 18 cases were detected by HRCT. False negative was seen associated with soft tissue density in mesotympanum (pars tensacholesteatoma). A
similar study\(^7\) had reported high sensitivity and specificity values, explaining scutum involvement was most commonly seen in early atticotemporal disease and is most commonly associated with pars flaccida cholesteatoma. Bernadette Koch et al\(^23\) in their book have quoted that scutum erosion occurs less commonly occurs in pars tensacholesteatoma.

All 12 cases detected tegmen erosion on HRCT showing high sensitivity and specificity of 100%. These findings are in concurrence with other studies\(^24\). However, in Mardassi Ali et al\(^16\) study had poor sensitivity of 60% and were mostly seen in pars tensacholesteatoma unlike 70% sensitivity reported in Prabhu et al\(^2\) study. Studies\(^17\) quoted that tegmen and dural plate erosion helps to decide surgical approach based on tympanic membrane and compartment involved.

Sinus tympani involvement was seen in 2 cases of which 1 case was detected on HRCT and thereby HRCT has less sensitivity 66.6% in the detection of sinus tympani involvement. These findings are in ordinance with another study\(^17\) with sensitivity of 72%. The true positive was seen associated with mesotympanum soft tissue density (pars tensacholesteatoma) and false negative was seen associated with epitympanum soft tissue density (parsflaccida cholesteatoma). Most of the false negatives were seen in pars flaccida cholesteatoma in other similar studies\(^17\). They quoted that sinus tympani is a delicate structure and difficult to visualize in the presence of cholesteatoma. But review articles\(^25,26\) quoted sinus tympani involvement was most common in pars tensacholesteatoma and is a common site of residual/recurrent cholesteatoma.

In the present study 5 out of 9 cases of facial canal dehiscence were detected on HRCT with less sensitivity 69.2% and good specificity 80%. Unlike in other studies\(^2,16\) had poor sensitivity, Zhang X et al\(^18\) had a low kappa value of (0.3-0.5) with poor sensitivity. In our study, false negatives in facial canal dehiscence were seen associated with soft tissue density in mesotympanum (pars tensacholesteatoma) in majority and 1 case in tubotympanic CSOM and most of the false negatives involved vertical segment of facial canal. One false positive was seen associated with mesotympanum soft tissue density (parsflaccida cholesteatoma) which involved the tympanic segment of facial nerve. Studies\(^24\) quoted that tympanic segment of facial nerve canal and part of vertical segment was most commonly missed due to the thin underlying bony floor. But mesotympanum soft tissue density usually makes it difficult to identify facial canal dehiscence due to the oblique orientation of scan and it is frequently difficult to locate the pathology\(^6,26\).

Semi-circular canal erosion was seen in 4 cases intraoperatively out of which 3 cases were diagnosed by HRCT. HRCT has a high sensitivity of 80% and specificity 100% in the detection of semi-circular canal erosion. Zhang X et al\(^18\) had good kappa value of 0.5 – 7. M D Prakash et al\(^24\) study had a sensitivity of 75% and specificity of 100%. In our study, one false negative in semi-circular canal erosion was seen associated with pars tensacholesteatoma. Bernadette Koch et al\(^23\) in their book have quoted that semi-circular erosion occurs more commonly in pars tensacholesteatoma and can be masked by mesotympanum soft tissue density. False negative was seen involving lateral and posterior semi-circular canal erosions. Sonika et al\(^12\) in their study had most of the false negatives involved the lateral semi-circular canal with a low sensitivity of 66.6% and lowest 25%.\(^9\).

In our study, 19 cases had mastoiditis intraoperatively out of which 18 cases were detected on HRCT. HRCT has a high sensitivity 95% and high specificity 100% in the detection of mastoiditis. Automastoidectomy was detected with 100% sensitivity. These findings were comparable with other studies \(^12\) had 100% sensitivity and specificity in detecting mastoiditis. False negative was seen in coalescentmastoiditis in atticotemporal type. A review article\(^25\) mentioned that coalescentmastoiditis is more commonly seen in atticotemporal/complicated mastoiditis. Sasmita et
al\textsuperscript{20} had good sensitivity in the detection of automasoidectomy.

In our study, HRCT had less sensitivity 75% and high specificity 85.7% in the detection of tympanic perforation. Hassmann Poznanaska et al\textsuperscript{22} in their study had a similar sensitivity (84%) and specificity (86%). In our study, majority of false negatives was seen in pars flaccid cholesteatoma with marginal perforation followed by tubotympanic CSOM. Similar findings were identified in other studies\textsuperscript{24,23}.

False positives (2 cases) were also seen with pars flaccida cholesteatoma (marginal perforation). Mariam Aljehani et al\textsuperscript{8} quoted that most of the false positives were due to prussack space involvement by cholesteatoma making it difficult to identify marginal perforations. False negatives in perforation were due to non-visualization either due to polyp or sagging meatalwall\textsuperscript{9}. HRCT in the present study has shown less sensitivity 72.2% and high specificity 100% in the detection of attic involvement. Majority false negatives were seen in tubotympanic followed by pars flaccida atticoantral CSOM. Sunitha Dashottar et al\textsuperscript{7} had a sensitivity of 50% and specificity 83% in their study. In a review study\textsuperscript{25} they have quoted that attic/aditus and antrum involvement can be seen in both pars tensa and pars flaccida cholesteatoma and can also be seen in tubotympanic CSOM.

In our study, HRCT has a less sensitivity 72.7% and high specificity 100% in the detection of aditus erosion. False negatives, (4 cases) were seen majority in atticoantral CSOM with pars flaccida cholesteatoma. Nanjaraj CP et al\textsuperscript{9} had a 92% sensitivity and 91% specificity. In our study, 15 cases had antrum involvement intra operatively with 10 cases detected on HRCT. HRCT has less sensitivity 75% and specificity 100% in the detection of antrum erosion. False negatives (4 cases) were seen majority in tubotympanic CSOM. A similar sensitivity of 88 % was seen in Tripathi Rai\textsuperscript{13} study.

Present study showed 4 cases of sigmoid plate erosion intra operatively out of which 2 cases were detected on HRCT. HRCT has 66.6% sensitivity and 100% specificity in the detection of sigmoid plate erosion. 2 False negatives were seen in atticoantral CSOM with cholesteatoma involving more than one compartment. These findings were similar to earlier study\textsuperscript{24} had a sensitivity of 85.7%. Mariam Aljehani et al\textsuperscript{8} in their study had 100% sensitivity and specificity and they also quoted that sigmoid plate erosion was seen most commonly with large cholesteatoma with extensive bony destruction.

Out of 5 cases with intracranial complications, 4 cases were detected on HRCT thereby exhibiting sensitivity 83.3% and specificity of 100% and these findings are similar with other studies\textsuperscript{9,13}. 80% of the intracranial complications were present in atticoantral CSOM, similar to Nanjaraj CP et al\textsuperscript{9} study with 100%. One false negative was seen in detection of petrous apicitis in tubotympanic CSOM with sclerosed mastoids. A review article\textsuperscript{25} reported petrousapicitis is more common in sclerosed mastoids and tubotympanic CSOM. In our study the most common intracranial complication was petrous apicitis 3.5% followed by cerebellar abscess 1.7%, meningitis 1.7% and skull base osteomyelitis (1.7%). But other studies have noted subperiosteal abscess(8%) was the most common intracranial complication\textsuperscript{13} and4% had brain abscess and mastoid abscess which were the other most common intracranial complications followed by temporal lobe abscess( 2%) and skull base osteomyelitis (2%).

In the present study, among the surgical cases, most of them were atticoantral followed by tubotympanic CSOM and HRCT has shown high sensitivity, specificity and PPV in the diagnosis of CSOM.

**Conclusion**

HRCT Temporal bone has a good sensitivity, specificity and accuracy in the diagnosis of type of CSOM with respect to surgical correlation (Gold standard) with significant p value (<0.05) in majority of the findings. It helps in detection of soft tissue density in middle ear and mastoid with...
great precision, its location and relation to adjacent structures. It has high sensitivity and specificity in the detection of cholesteatoma, ossicular and other bony erosions and intracranial complications.

However, it faces its own challenges in the characterization of soft tissue density, facial canal dehiscence and tympanic membrane perforation. HRCT Temporal bone provides a great deal of information which is extremely useful for confirming the diagnosis of CSOM, treatment planning and surgical approach, making it an essential pre work up diagnostic tool and a road map for surgery.

Hence, this study suggests that HRCT of Temporal Bone should be recommended for all cases of CSOM to evaluate the extent, possible complications of the disease and for appropriate management.
