Abstract

Background and Objectives: The Introduction of Helical CT is one of many recent advances which create improvement in the detection and characterization of renal masses and compare the enhancement of renal mass and cortex and to evaluate the enhancement of renal veins and inferior vena cava during corticomedullary and nephrographic phase.

Methods: Study included 33 cases of renal masses was done for a period of 1 year from Nov 2018 to November 2019 in the department. Patients were evaluated thoroughly.

Results and Conclusions: For the final analysis thirty two patients were included (19 males and 13 females). Thirty three lesions were detected in thirty two patients. Of these, thirty lesions were neoplastic lesions of which majority of the neoplastic lesion comprised of Renal cell carcinoma (22 cases), Transitional cell carcinoma (3 cases), Angiomylipoma (1 case), Renal oncocytoma (1 case), Renal metastasis (1 case), Renal abscess (1 case) and three lesions were cystic lesions.
1. Renal neoplasm showed greater enhancement in the nephrographic phase compared with that in corticomedullary phase (p=.001).
2. Renal cortex also showed greater enhancement in the nephrographic phase compared with that in corticomedullary phase (p=.001).
3. Renal vein are best visualized in corticomedullary phase and inferior vena cava is better visualized in nephrographic phase.

Introduction

Helical CT created many advances in the detection and characterization of renal masse. Helical CT is considered as the state of the art technology in the evaluation of abdominal pathology. It is modality of choice for suspected renal mass, its staging and detection of distinct metastases. Reason behind that are low cost, high accuracy and ready accessibility.

The commonest space occupying renal lesion is a simple cyst with an incidence of 25% - 50% after the age of 50 years. Benign renal masses outnumber the malignant ones. Renal cell carcinoma is the most common tumor of the kidney comprising 3% of all malignancies found in adults.

The overall diagnostic accuracy of properly performed CT for separating cyst from neoplasms extremely high.

Helical CT has many potential advantages over conventional axial CT. At the most commonly used pitch (ratio of table speed to image collimation) of 1:1, most kidneys can be scanned using narrow (5 mm) image collimation in less than 30 seconds. Such
positioning improves the accuracy of range of interest measurements and the imager's ability to characterize a lesion by minimizing partial volume effects. The rapid scanning time of helical CT also permits renal imaging during any of the three phases of renal parenchymal contrast material enhancement: the cortical phase, nephrographic phase, or excretory phase.

**Aims and Objectives of the Study**
- To study the diagnostic accuracy of Helical CT in detection and characterization of renal masses.
- To compare the enhancement of renal neoplasm and renal cortex during corticomedullary and nephrographic phase.
- To evaluate the enhancement of renal veins and inferior vena cava during corticomedullary and nephrographic phase.

**Methodology**
All patients referred to the department of Radio diagnosis with clinically suspected Renal mass lesions in a period of 1 years from Nov 2018 to November 2019 will be subjected for the study.

The study includes
- All patients clinically suspected to have Renal mass lesions.
- All patients with incidentally diagnosed renal masses by ultrasound.
- Cases of all age groups irrespective of sex.

The study will exclude
- Patient having history of trauma.

The pathological lesions were evaluated with respect to pre and post contrast attenuation values, the size, location of the mass, presence of calcification, presence of fat, and extension into the adjoining structures.

All CT diagnosis were obtained by a consensus of two senior radiologists.

**Results and Discussion**
In the present study, there were twenty males and thirteen females.

For the final analysis thirty two patients were included (19 males and 13 females).

Thirty three lesions were detected in thirty two patients. Of these, thirty lesions were neoplastic lesions and three lesions were cystic lesions.

The visibility of renal veins and inferior vena cava was assessed in corticomedullary and nephrographic phases. Renal veins were better visualized in corticomedullary phase and inferior vena cava was better visualized in nephrographic phase.

The statistical significance of both renal neoplasms and normal renal cortex enhancement...
in the nephrographic and corticomedullary phases were calculated using student t test. Both renal neoplasms and renal cortex showed significantly greater enhancement in the nephrographic phase compared with that in the corticomedullary phase (p=.001 and p=.001 respectively).

**Images 1:** Phases of renal enhancement at multidetector CT. (a) Unenhanced axial CT at level of renal hilum. (b) Late arterial phase axial CT at level of renal hilum. There is good opacification of the left renal artery (black arrow) and vein (white arrow). (c) Nephrographic phase axial CT at level of renal hilum. (d) Excretory phase axial CT at level of renal hilum.

**Images 2a and 2b**
A Bosniak type II cyst with uniform high attenuation, no enhancement is seen.
B Well defined focal anechoic lesion in lower pole of left kidney-USG
Discussion

The widespread use of USG and CT for survey examinations of abdomen has resulted in an increased rate of detection of both neoplastic and non-neoplastic renal masses. Previous studies\(^1,2,3\) have shown that nephrographic and excretory phase images are superior to corticomedullary phase in the detection of renal masses. Cohan et al\(^4\) demonstrated that small medullary lesions may be missed on corticomedullary phase and that false-positive medullary pseudolesions may be detected due to disparate enhancement of medulla compared with that of the adjacent cortex.

Renal cortical enhancement in the nephrographic phase is more than that in the corticomedullary phase in all patients. These results correlated with the study conducted by Birnbaum et al\(^1\). But our results are different from the study conducted by Cohan et al\(^3\), and Szolar et al\(^2\).

Cohan et al\(^3\) studied cortical enhancement in corticomedullary and nephrographic phases. Mean attenuation of renal cortex in their study was 147 ± 41 HU on corticomedullary phase images and 117 ± 41 HU on nephrographic phases images. They found that mean attenuation was 30 HU greater in corticomedullary phase than in nephrographic phase images. In Szolar et al\(^2\)'s study, mean cortical attenuation was 185 ± 35 HU in corticomedullary phase and 168 ± 33HU in nephrographic phase. In their study, although mean cortical enhancement was slightly greater in corticomedullary phase images than that in nephrographic phase images, this was not statistically significant.

Analysis of summary enhancement data revealed that both renal neoplasms and normal renal cortex demonstrated significantly greater enhancement in the nephrographic phase compared with that in the corticomedullary phase (p=.001 and .01 respectively). No statistically significant differences (p > 0.5) in enhancement were noted for the radiologically benign cysts when the two phases are compared. These results correlated with study conducted by Birnbaum et al\(^1\).

Images 3: Renal cell carcinoma - CT

a NECT showing soft tissue exophytic mass in left kidney
b Lesion shows enhancement on contrast administration
c Another case of RCC showing areas of calcification.
Conclusion
1. Renal neoplasm showed greater enhancement in the nephrographic phase compared with that in corticomedullary phase (p=.001).
2. Renal cortex also showed greater enhancement in the nephrographic phase compared with that in corticomedullary phase (p=.001).
3. Renal vein are best visualized in corticomedullary phase and inferior vena cava is better visualized in nephrographic phase.

The enhancement values of Renal masses on contrast enhanced CT in nephrographic phase, corticomedullary phase determines the vascularity of the mass and hence determines the nature of the lesion.

Therefore, this study proves that Multiphasic Helical CT is a first line of investigation for determining the indeterminate lesion in comparison to other modalities.
